Abstract: Metastatic cholangiocarcinoma (CCA) to the gastrointestinal tracts has rarely been described in the literature. We report a 54-year-old male patient with radical resection of an extrahepatic CCA who underwent uncommon metastatic pattern. After a recurrence-free period of 2 years, an elevated CA19-9 initiated a CT scan, showing a tumor at the junction of rectum and sigmoid with enlarged lymph nodes around colon, mimicking a primary colon cancer. Histological diagnosis was adenocarcinoma, and the patient was treated with surgery as a primary colon cancer, but post-operative immunohistochemistry revealed the same pattern as the CCA. As colon is not the common organ for distant spread that makes some challenge to distinguish the colonic metastatic CCA between primary colon carcinoma. Biomarkers (CA 19-9), immunohistological and pathological features play an important role in distinguishing CCA from primary colon cancer. This case taught us a lesson how cancers can spread to unusual sites and mimic other tumor types, that may change the treatment and prognostication significantly.

Introduction

Cholangiocarcinoma (CCA) is a high degree of malignant cancer arising from anywhere from the intrahepatic to the extrahepatic biliary epithelium. Clinically, most patients with CCA are advanced stage when diagnosed due to the highly aggressive ability. Only a few cases are diagnosed at the early stage which can be treated by surgical resection while majority of them will recurrent or metastasize to other organs during a short time after operation. Lungs, adrenal glands, liver as well as lymph nodes are the common metastatic sites via the lymphatics or vascular. Metastatic CCA of the colorectum is rare with only sporadic cases reported until now. Here we present a case of colonic metastatic adenocarcinoma in a patient with 2-year history of extrahepatic CCA radical resection.

Case presentation

A 54-year-old male patient underwent the hepatic left lobe and tumor resection after a hepatic portal tumor with intrahepatic bile ducts prominence found by CT scan in January 2015 (Figure 1). The surgical specimens contained a solitary gray mass located at hepatic portal, 3×2×2 cm in size. Cancer tissue infiltrated ductus hepaticus communis, left and right hepatic ducts, hepatic tissue. Pathological
results showed a well differentiated adenocarcinoma (Figure 2). There was one in two lymph nodes metastasis around the liver with microvascular and nerve invasion.

The patient had no signs of recurrence over the next 2 years until a high level of CA19-9 (162.36 U/mL) was detected in January 2017. A contrast-enhanced CT showed a submucosa eminent lesion at the junction of rectum and sigmoid with enlarged lymph nodes around colon (Figure 3). Examination of the colonoscopic biopsy revealed adenocarcinoma. The patient received colon tumor resection and lymph nodes dissection after considered as a case of colonic primary adenocarcinoma. The final pathological results showed a well differentiated adenocarcinoma and the mass mainly existed serosa with infiltrating to submucosa and mucosa (Figure 2).

Immunohistochemical staining was positive for cytokeratin (CK)-19 (strong), CK-20 (weak) and villin (weak) while negative for CK-7 and CDX-2, which were consistent with the hepatic portal carcinoma resected 2 years ago (Figure 2). At last, the colonic tumor was diagnosed metastasis from hepatic portal CCA according to the expression of the above molecular markers and pathological results.

The disease progressed 1 month later, which was convinced by an enlarged anterior pancreatic lymph node in CT scan. The patient refused to receive chemotherapy and he was giving only support care. In June 2016, the patient died due to broader spreading of cancer.

**Discussion and conclusions**

Most of colonic tumors originate from colonic epithelium with the feature of metastasis to other organs such as liver and hepatic portal lymph nodes. The reported cases of metastatic colonic malignancy from liver or bile ducts were extremely rare. CCA as a kind of cancer arising from biliary epithelium can be treated with resection during early stage but easily recurrent. Liver, lung, and lymph nodes are common metastatic sites instead of colon (1). Only seven cases of colonic metastasis CCA have been described on the literature so far. Therefore, this pattern of distant metastasis has been less understood. Initially, Wakahara reported a male patient with intrahepatic cholangiocarcinoma (ICC) with sigmoidectomy metastasis in 2005 (2). The other six cases were reported in the year of 2010, 2011, 2012, and 2016, respectively (Table 1) (3-8). The mean age of these patients is 63.6 (range, 57–76). Five of them were diagnosed...
with ICC, and two with extrahepatic cholangiocarcinoma (ECC). Four in seven patients confirmed to be colonic metastatic CCA when the primary cancer diagnosed. Three cases metastasized to colon after the primary cancer resection for 5, 6 years and 15 months respectively, which is similar to current patient.

Based on the features of these limited cases, we identified some differences between colonic primary cancer and metastatic disease. Endoscopically, the secondary colonic cancer lesions consist of multiple discrete submucosal nodularity with intact mucosa. The submucosal infiltration by metastatic cancer often forms stricture, which is

ICC, intrahepatic cholangiocarcinoma; ECC, extrahepatic cholangiocarcinoma; CBD, common bile duct.
unlike to primary colon cancer originating from mucosa with radial extension assuming bleeding ulceration or loss of lobulation (9). Histopathological examination often reveals adenocarcinoma. Tumor mass mainly exists in the subserosa and colonic wall with infiltrating to submucosa and mucosal, which is contrary to primary cancer rising from mucosa with outward spreading. Immunohistochemistry is the most reliable feature to distinguish colonic primary adenocarcinoma from metastatic CCA to colon. However, there is no specific or sensitive protein to confirm the origin site. Usually, CK-7 positive with CK-20 negative or weakly positive suggests the tumor rising from pancreaticobiliary (10) (Table 2). Similarly, CK-19 strongly positive with CDX-2 negative also indicates the tumor comes from biliary tract instead of colorectum. However, these markers should be read and judged comprehensively.

It is difficult to distinguish colonic recurrence of CCA from a primary colon cancer in this patient based on the preoperative clinical, endoscopic and radiologic features. That is because primary colon cancer occurs more commonly than secondary one. After the second operation, we diagnosed colon metastasis from CCA for the following reasons. Firstly, there were no other primary site of metastatic adenocarcinoma was found by gastrointestinal endoscopy and CT scan. Secondly, the cancer mass infiltrated heavily on colonic wall than mucous, which eliminate the tumor arose from later. Thirdly, the colonic tumor expressed CK19 strongly positive and CDX-2 negative, suggesting the biliary tract origin instead of colon. Last, the colonic mass had similar immunohistochemical characteristics to the primary CCA.

In a conclusion, the cases of colonic metastatic CCA are extremely rare and easily misdiagnosed as a second primary colon adenocarcinoma. In retrospect, this signifies the importance of differential diagnosis immunohistochemistry and other modalities to avoid unnecessary over treatment.
